Geib T, Moghaddam G, Supinski A, Golizeh M and Sleno L (2021) Protein Targets of Acetaminophen Covalent Binding in Rat and Mouse Liver Studied by LC-MS/MS. *Front. Chem.* 9:736788. doi: 10.3389/fchem.2021.736788

Acetaminophen (APAP) is a mild analgesic and antipyretic used commonly worldwide. Although considered a safe and effective over-the-counter medication, it is also the leading cause of drug-induced acute liver failure. Its hepatotoxicity has been linked to the covalent binding of its reactive metabolite, *N*-acetyl *p*-benzoquinone imine (NAPQI), to proteins. The aim of this study was to identify APAP-protein targets in both rat and mouse liver, and to compare the results from both species, using bottom-up proteomics with data-dependent high resolution mass spectrometry and targeted multiple reaction monitoring (MRM) experiments. Livers from rats and mice, treated with APAP, were homogenized and digested by trypsin. Digests were then fractionated by mixed-mode solid-phase extraction prior to liquid chromatography-tandem mass spectrometry (LC-MS/MS). Targeted LC-MRM assays were optimized based on high-resolution MS/MS data from information-dependent acquisition (IDA) using control liver homogenates treated with a custom alkylating reagent yielding an isomeric modification to APAP on cysteine residues, to build a modified peptide database. A list of putative *in vivo* targets of APAP were screened from data-dependent high-resolution MS/MS analyses of liver digests, previous *in vitro* studies, as well as selected proteins from the target protein database (TPDB), an online resource compiling previous reports of APAP targets proteins. Multiple protein targets in each species were found, while confirming modification sites. Several proteins were modified in both species, including ATP-citrate synthase, betaine-homocysteine *S*-methyltransferase 1, cytochrome P450 2C6/29, mitochondrial glutamine amidotransferase-like protein/ES1 protein homolog, glutamine synthetase, microsomal glutathione *S*-transferase 1, mitochondrial-processing peptidase, methanethiol oxidase, protein/nucleic acid deglycase DJ-1, triosephosphate isomerase and thioredoxin. The targeted method afforded better reproducibility for analysing these

Abbreviations: ACN, acetonitrile; APAP, acetaminophen; BHMT, betaine—homocysteine *S*-methyltransferase 1; CA3, carbonic anhydrase 3; CAM, carbamidomethylation; CPS1, mitochondrial carbamoyl-phosphate synthase [ammonia]; DTT, dithiothreitol; ER, endoplasmic reticulum; EST, estrogen sulfotransferase; GS, glutamine synthetase; HDAG, hepatitis delta antigen; HP-CAM, *N*-(4-hydroxyphenyl)-2-carbamidomethylation; HP-IAM, *N*-(4-hydroxyphenyl)-2-iodoacetamide; 3 α -HSD, 3- α -hydroxysteroid dehydrogenase; IAM, iodoacetamide; IDA, information-dependent acquisition; IP, intraperitoneal; LC-MS/MS, liquid chromatography-tandem mass spectrometry; MeOH, methanol; MGST1, microsomal glutathione *S*-transferase 1; MRM, multiple reaction monitoring; MTO, methanethiol oxidase; NAPQI, *N*-acetyl *p*-benzoquinone imine; PMPCB, mitochondrial-processing peptidase subunit beta; SDS, *n*-dodecyl sulfate; *S*/*N*, signal-to-noise; SPE, solid-phase extraction; TPDB, Target Protein Database; TPI, triosephosphate isomerase; TXN, thioredoxin.

low-abundant modified peptides in highly complex samples compared to traditional data-dependent experiments.

Q8

Q9 INTRODUCTION

Drugs are generally metabolized by the liver into biologically inactive forms and eliminated from the body through bile and urine. However during these processes, they can also be bioactivated by hepatic enzymes into reactive electrophilic intermediates and subsequently react with nucleophilic sites of proteins to form covalent adducts (Xu et al., 2005; Park et al., 2011). Reactive metabolites can in turn cause oxidative stress, depleting intracellular glutathione, and affect energy metabolism by binding to mitochondrial protein complexes (Pessayre, 1995; Srivastava et al., 2010).

Acetaminophen (*N*-acetyl *p*-aminophenol, APAP) is one of the most commonly used analgesic and antipyretic, and is known to be the number one cause of acute liver failure in North America (Bateman, 2016). APAP is deemed safe as long as recommended doses are not exceeded, but very high doses can cause severe hepatotoxicity, liver injury and even death in both children and adults (Tittarelli et al., 2017). APAP metabolism primarily occurs in the liver, where major biotransformations include sulfate and glucuronide conjugation forming readily excretable phase II metabolites. A smaller proportion, between 10 and 15%, is converted to the reactive electrophile *N*-acetyl *p*-benzoquinone imine (NAPQI), by multiple cytochrome P450 enzymes (Laine et al., 2009). NAPQI can generally be detoxified *via* glutathione conjugation and further excreted *via* the mercapturic acid pathway. However, excess NAPQI can bind to nucleophilic sulfhydryl groups in cysteines of cellular proteins, leading to possible protein dysfunction due to conformational changes, potentially leading to acute liver failure (James et al., 2003; Graham and Scott, 2005). Mitochondrial protein adducts have been shown to directly correlate to the initiation of hepatotoxicity through mitochondrial dysfunction and DNA fragmentation (Tirmenstein and Nelson, 1989; McGill et al., 2012; McGill et al., 2014; Xie et al., 2015; Ramachandran and Jaeschke, 2020). Identifying and monitoring modified proteins from *in vivo* samples could help better understand the metabolic processes involved in APAP-related hepatotoxicity and potentially lead to the detection of important biomarkers (Cohen et al., 1997; Bissell et al., 2001).

In this study, liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) was employed to identify *in vivo* protein targets of acetaminophen, *via* the formation of NAPQI, in mouse and rat. Liver homogenates were digested by trypsin and fractionated by mixed-mode solid-phase extraction (SPE) prior to LC-MS/MS analysis. A scheduled multiple reaction monitoring (MRM) was developed based on data-dependent LC-MS/MS results as well as previous reports of APAP-modified proteins, while using a custom alkylation reagent to prepare isomerically-modified peptides from liver

homogenates. This comparative analysis in rat and mouse could potentially provide novel mechanistic insight into APAP-related hepatotoxicity.

MATERIALS AND METHODS

Chemicals and Materials

Urea was purchased from BioRad (Mississauga, ON, Canada). APAP, trypsin (TPCK-treated, from bovine pancreas), sodium *n*-dodecyl sulfate (SDS), dithiothreitol (DTT), iodoacetamide (IAM), thiourea, ammonium bicarbonate, ammonium acetate, ammonium hydroxide, formic acid, acetic acid, acetonitrile (ACN), methanol (MeOH) and all other reagents were from Sigma-Aldrich (St. Louis, MO, United States). Labeling agent *N*-(4-hydroxyphenyl)-2-iodoacetamide (HP-IAM) was synthesized in-house as previously described (LeBlanc et al., 2014). Ultra-pure water was produced using a Millipore Synergy UV system (Billerica, MA, United States).

In Vivo Experiments

Four Sprague-Dawley male rats (450–550 g) were dosed with 600 mg/kg APAP (IP; solubilized in 60% PEG 200) or two animals were treated with vehicle for control samples. Rat livers were collected after 24 h post dosing. Male C57BL/6 mice (27–35 g) were treated (IP, in saline) with 150 mg/kg (2 and 6 h) and 300 mg/kg (2 and 6 h), as well as with vehicle for control samples. Two mice were treated at each dose and timepoint. All experiments were performed at INRS Centre National de Biologie Expérimentale (Laval, QC, Canada). The protocol was approved by the Ethics Committee of the INRS Centre National de Biologie Expérimentale under the ethical practices of the Canadian Council on Animal Care (project UQLK.14.02).

Sample Preparation

Frozen liver samples, stored at -80°C , were homogenized in 100 mM ammonium bicarbonate (ABC buffer, pH 8–8.5) at 5 ml/g tissue weight using a hand-held homogenizer (Tissuemiser; Thermo Fisher Scientific, Waltham, MA, United States), and 100 μl aliquots were combined with 25 μl of 0.1% SDS, and heated for 5 min at 95°C . After cooling samples, 50 μl of a solution of 7 M urea and 2 M thiourea in water was added, and a probe sonicator was used (XL-2000; Qsonica, Newtown, CT, United States) for three cycles of 10 s, followed by another 15 min in an ultrasonic bath (Branson 2510; Branson Ultrasonics, Brookfield, CT, United States). The resulting protein extract was then diluted with 500 μl of 100 mM ABC buffer. Reductive alkylation was performed by adding DTT (30 μl , 100 mM; 37°C for 20 min), followed by IAM (45 μl , 100 mM;

37°C for 30 min in the dark). Similarly, control samples, from vehicle-treated animals, were alkylated using HP-IAM (by simply substituting the IAM mentioned above). Samples were then digested by trypsin (30 µl, 1 mg/ml; 37°C for 18 h), followed by the addition of 300 µl of 2% formic acid prior to fractionation by solid phase extraction (SPE) on OASIS MCX cartridges (1 cc, 30 mg; Waters, Milford, MA, United States). Loaded cartridges were washed in three steps with 2% formic acid in water, 100% MeOH and 50% MeOH (1 ml each). Eight fractions were collected by eluting with 15, 20, 25, 35, 50, and 200 mM ammonium acetate in 50% MeOH, then 0.1 and 3% ammonium hydroxide in 50% MeOH (1 ml each). Fractions were dried under vacuum and stored at -30°C until analysis.

LC-MS/MS Analysis

SPE fractions were reconstituted in 100 µl 10% acetonitrile and injected (20 µl) onto an Aeris PEPTIDE XB-C18 column (100 × 2.1 mm, 1.7 µm) (Phenomenex, Torrance, CA, United States) using a Nexera UHPLC system (Shimadzu, Columbia, MD, United States) with water (A) and ACN (B), both containing 0.1% formic acid, at a flow rate of 300 µl/min (at 40°C). The elution gradient started at 5% B for 2.5 min, and was linearly increased to 30% B in 47.5 min, to 50% B in 5 min, then to 90% B in 1 min, held for another 4 min at 90% B.

Data-dependent experiments were performed to collect MS and MS/MS spectra on a high-resolution quadrupole-time-of-flight TripleTOF 5600 mass spectrometer (Sciex, Concord, ON, Canada) equipped with a DuoSpray ion source in positive electrospray mode set at 5 kV source voltage, 500°C source temperature and 50 psi GS1/GS2 gas flows, with a declustering potential of 80 V. The instrument performed a survey TOF-MS acquisition from m/z 140–1250 (250 ms accumulation time), followed by MS/MS on the 15 most intense precursor ions with a minimum intensity of 250 cps from m/z 300–1250. Precursor ion were excluded for 20 s after two occurrences in data-dependent acquisition (DDA) mode with dynamic background subtraction. Each MS/MS acquisition (m/z 80–1500, high sensitivity mode) had an accumulation time of 50 ms and collision energy of 30 ± 10 V, with a total cycle time was 1.05 s. The MS instrument was calibrated at every four injections using an in-house calibration mix. Analyst TF software (1.7.1; Sciex) was used for data acquisition and raw data was visualized with PeakView 2.2 with Masterview 1.1 (Sciex). The mass spectrometry proteomics data from high-resolution data-dependent experiments have been deposited to the ProteomeXchange Consortium *via* the PRIDE (Perez-Riverol et al., 2019) partner repository with the dataset identifier PXD027674 and 10.6019/PXD027674.

Targeted assays were developed using scheduled LC-MRM on a Sciex QTRAP 5500 hybrid quadrupole-linear ion trap system with a TurboIonSpray ion source in positive mode, with identical UHPLC conditions as for data-dependent high resolution experiments. Source parameters were as follows: ionspray voltage 5 kV; temperature 550°C; GS1 and GS2 50 psi; and curtain gas 35 psi. Declustering, entrance and collision cell exit potentials were set at 80, 10 and 13 V, respectively. Collision-induced dissociation was performed at a collision energy of 30 V.

Scheduled MRM time windows were set at 240 s, with a targeted scan time at 1.25 s. Minimum and maximum dwell times were 10 and 250 ms, respectively. MRM transitions monitored for SPE fractions two to eight can be found in **Supplementary Tables S1, S2**, for rat and mouse, respectively. Sciex Analyst software 1.7 was used for data acquisition.

Data Processing

Raw data files from quadrupole-time-of-flight experiments were searched against the rat or mouse UniProtKB/Swiss-Prot protein database (release date: 07/18/2018, including common protein contaminants) using Sciex ProteinPilot 5.0. To detect APAP covalent adducts, a custom modification was added to the Paragon algorithm (Shilov et al., 2007) with a probability of 50% for APAP modification on cysteine residues (C₈H₈NO₂ replacing H, $\Delta m = +149.04766$ u). The search was performed for +2 to +4 charge states at a MS tolerance of 0.05 u on precursor ions and 0.1 u on fragments. For protein identifications, a target-decoy approach was applied at a 1% false discovery rate (Aggarwal and Yadav, 2016). From the list of identified APAP-modified peptides, those with spectral confidence less than 95% were removed, as were those with modifications other than APAP and cysteine carbamidomethylation (CAM).

LC-MRM peaks were integrated and verified using MultiQuant 3.0.2 (Sciex) to ensure that APAP-modified peptides matched with *N*-(4-hydroxyphenyl)-2-carbamidomethylated (HP-CAM) peptides from control samples. Confirmation of a modified peptide was based on the following criteria: 1) signal-to-noise (S/N) of all transitions above 10; 2) ≤20% deviation of relative abundance (*see Eq. 1*) (Geib et al., 2019) for the first transition and ≤30% deviation for second and third transitions) from HP-CAM-modified peptide standard; and 3) within 60 s of the corresponding HP-CAM peptide's retention time, to correct for small drifts in RT over the acquisition batch.

$$\text{Relative abundance} = \frac{A_X}{\sum_{i=1}^3 A_i} \quad (1)$$

APAP-modified peptides with multiple cysteines, containing at least one CAM-cysteine, did not meet the second (or third) criteria, due to no standard samples available for comparison (all cysteines were HP-CAM modified in reference samples). Therefore, confirmation for these modified peptides incorporated into the MRM method was achieved by the absence of corresponding signals in HP-CAM reference samples.

RESULTS

The goal of this study was to assess the applicability of a targeted LC-MS/MS method for *in vivo* biomonitoring of liver protein adducted by reactive metabolites in multiple samples from rat and mouse, and to compare the results obtained *via* data-dependent high-resolution MS/MS assays. With the aim of identifying low abundant APAP-modified peptides in this highly complex biological matrix, tryptic digests were fractionated by mixed-mode solid-phase extraction. These

*APAP modification site.

fractions were subjected to data-dependent high-resolution tandem mass spectrometry (HRMS/MS) analyses as well as targeted MRM assays, and results from these analyses were compared.

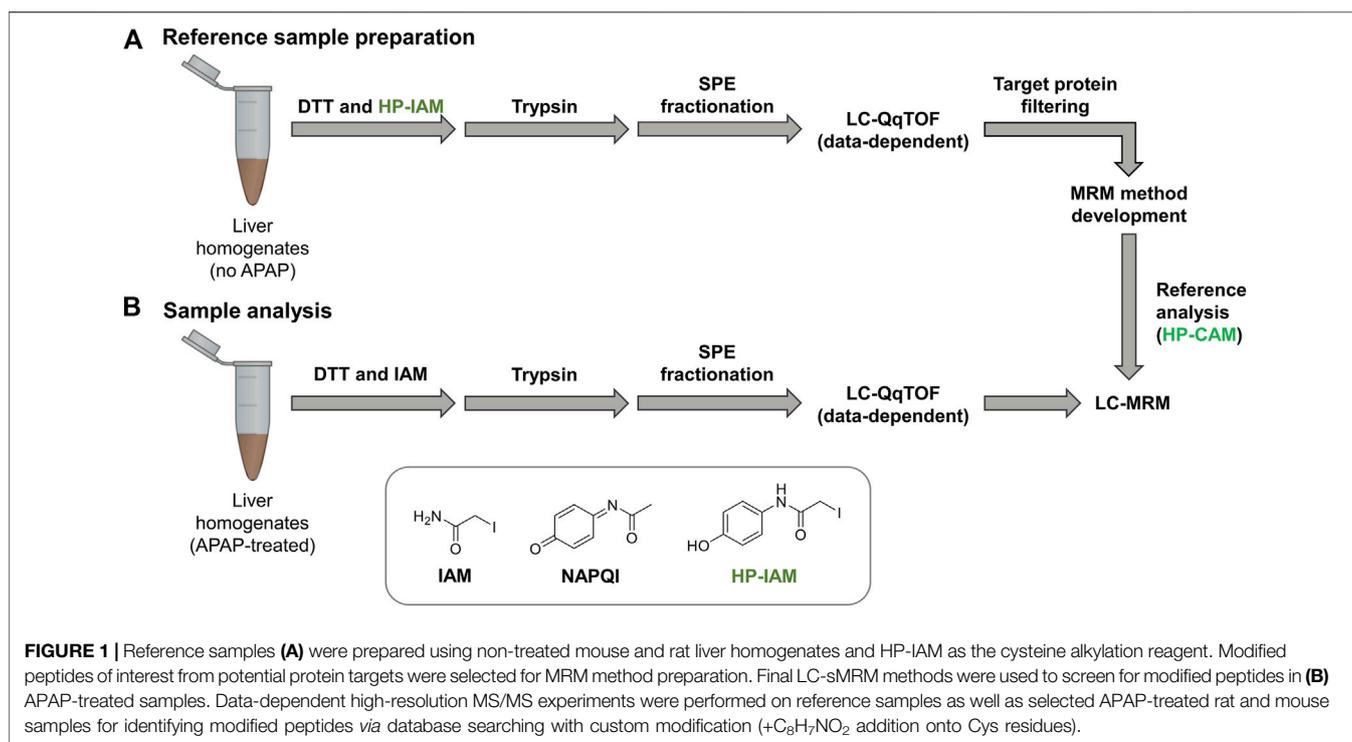

Detection of APAP Protein Targets via High-resolution Data-dependent MS/MS

Four liver digests from each species were initially subjected to untargeted high-resolution MS/MS to identify potentially novel target proteins. In total, 15 APAP-modified mouse peptides (from 14 target proteins) were identified (with over 95% peptide confidence). These included five peptides with more than one cysteine, one being APAP-bound and the other(s) carbamidomethylated, however the exact location of the APAP modification was possible in each case, based on unique y and b-ions in their high-resolution MS/MS spectra. A specifically challenging example was seen for peptides KPIGLC¹⁷⁴C¹⁷⁵IAPVLAAK and C¹⁷⁴C¹⁷⁵IAPVLAAK from

glutamine amidotransferase-like class 1 domain-containing protein 3A (and its rat ES1 protein homolog) (*see Supplementary Figure S1*), where the APAP modification could be pinpointed was on Cys175. From the rat liver digests, 17 distinct peptides were identified as APAP-modified from 16 proteins. Interestingly, the modified peptide found from triosephosphate isomerase in rat, which has two cysteine residues (CLGELICTLNAAK), was detected both as singly and doubly APAP-modified. A summary of all APAP-modified peptides identified from data-dependent experiments can be found in **Table 1**. From these experiments, several protein orthologs were found in both rodent species, modified at the same cysteine site.

Building HP-CAM-Peptide Standard Library

Control liver samples were alkylated with hydroxyphenyl iodoacetamide (HP-IAM) prior to trypsin digestion, SPE fractionation and data-dependent LC-MS/MS analysis (*see Figure 1*). HP-CAM modification yields a positional isomer of

Q19

APAP-modification on all cysteines and modified peptides were identified using the same criteria as APAP-modified peptides from database searching. In total, 1466 HP-CAM-modified proteins with 4554 distinct HP-CAM peptides were identified in the mouse control sample; and 1073 HP-CAM-modified proteins with 3599 distinct HP-CAM-peptides were found in the rat control sample. The resulting list of HP-CAM peptides was further filtered to include peptides of a select list of potential protein targets. These rat and mouse protein targets were based on our data-dependent results, as well as previous APAP *in vitro* binding studies (Golizeh et al., 2015; Geib et al., 2019), and additional APAP protein targets found in the Target Protein Database (TPDB) (Hanzlik et al., 2020). The resulting filtered HP-CAM-peptide list contained information on which SPE fraction contained the identified peptide, as well as peptide retention time, charge state, and its three most intense fragment ions (preferably with fragment $m/z >$ precursor m/z). These target peptides selected for MRM analysis are in **Supplementary Table S3**.

Scheduled MRM methods were built, with three transitions per peptide, and separated based on species and SPE fraction. MRM transitions of modified peptides were also monitored in adjacent fractions as those where they were detected in HP-CAM samples, since peptides can often elute in more than one fraction. In the case of two peptides from mouse glutamine amidotransferase and rat ES1 protein homolog, where one Cys was APAP-modified and the other was carbamidomethylated, retention times and fragment ions from data-dependent MS/MS were used to build the MRM method. Unfortunately, several other peptides with multiple cysteines were not monitored by MRM as their signals were not confirmed when developing the targeted method.

Detection of APAP-Peptides *via* LC-MRM

APAP-treated and HP-CAM alkylated liver digests were analyzed by scheduled LC-MRM methods specific to each SPE fraction. LC-MRM peaks were integrated, and relative peak areas for each transition (transition/sum of all transitions) as well as retention times were compared with HP-CAM signals for the same peptide. **Figure 2** shows a representative example of a confirmed target LC-MRM for a mouse CYP 2C29 peptide, found *via* data-dependent MS/MS and confirmed by MRM analyses. The analogous peptide in rat CYP2C7 was also confirmed *via* data-dependent MS/MS and LC-MRM. **Figure 2** also shows the example of the tryptic peptide with two cysteines, but only one of them being APAP-modified, from mouse mitochondrial glutamine-amidotransferase-like 1 domain-containing protein 3A and rat mitochondrial ES1 protein homolog. Remarkably, the non-tryptic peptide containing the same modified cysteine was found in our data-dependent analyses in both species, as well as screened for during LC-MRM analyses, with the same modification site being confirmed in all liver samples. These modified peptides were confirmed based on the absence of a corresponding signal in HP-CAM-control samples.

From eight APAP-treated mouse livers (two animal each at 150 and 300 mg/kg, either 2 and 6 h post dose), LC-MRM confirmed 13 distinct APAP-modified sites from 13 different proteins. From **Table 2**, the distribution of these confirmed targets is shown for each dosing regime, with many of them being confirmed in all samples, and five being detectable only at the 300 mg/kg dosing level. The two dosing levels at 150 and 300 mg/kg in mouse were chosen since this species is known to be more susceptible to APAP-related hepatotoxicity, compared to rat which could tolerate the higher dose at 600 mg/kg. *APAP modification site. Underlined peptides (or modification sites) were also identified in data-dependent MS/MS experiments.

^aIdentified based on an absent signal in the reference (HP-CAM) sample.

previous work, it was found that at 600 mg/kg dose in rat, APAP-albumin adducts did not decrease over the 24 h (LeBlanc et al., 2014), however, shorter timepoints (2 and 6 h) were chosen for mouse since they exhibit higher toxicity.

From the analysis of four rat liver samples, 23 distinct APAP-peptides were confirmed, from 21 different proteins (Table 3). Two proteins were close homologs, CYP 2C6 and 2C7, with very similar

peptide sequences, though the 2C6 peptide was found via LC-MRM only in one animal, compared to the 2C7 modified peptide being well detected in all rat livers. Two peptides with the same modification site were found for the ES1 protein homolog in all rats. Methanethiol oxidase also had two modified cysteine sites, though one was detectable in only one rat liver, whereas the one modified at Cys8 was detected in all rat livers, as well as in five of

*APAP modification site. Underlined peptides were also identified in data-dependent MS/MS experiments (^awith inclusion list).

eight mice, including all livers at the 300 mg/kg dose. Also in mouse, a very similar protein, selenium-binding protein 2, was modified at the same cysteine site, with a peptide differing only by one amino acid, in three of four mice at the higher dose. Another interesting example is that of triosephosphate isomerase, which was found to have one peptide having two APAP-modified cysteines by data-dependent analyses. LC-MRM results confirmed this doubly modified peptide in all four rat livers. As shown in Table 1, the same peptide with only one cysteine modified was also identified from rat as well as the singly modified mouse peptide, however these peptides were not screened for by LC-MRM. The mouse peptide specifically was a very long peptide with 33 residues and a charge state of 4+, making it quite difficult to screen for via LC-MRM without a corresponding signal in the HP-CAM reference sample. Another example of a target protein found in both species via data-dependent HRMS/MS analyses only is protein/nucleic acid deglycase DJ-1 (also known also Parkinson disease protein 7 homolog), with an identical peptide in mouse and rat incorporating two cysteines, one of which was APAP-modified. This large peptide was not easily amenable to MRM analysis due to the lack of significantly intense fragment ions, as well as no appropriate HP-CAM peptide for method optimisation. LC-MRM data with integrated peak areas and retention times from all samples have been made available in Supplementary Table S4.

Inclusion List High-resolution MS/MS for APAP-Modified Peptides

All APAP-modified peptides detected via LC-MRM not detected by data-dependent analyses were screened a second time by

incorporating an inclusion list for targeted precursor ions. The same fractions with confirmed LC-MRM hits were analyzed. Only one modified peptide was ultimately detected with sufficient spectral confidence >95% (see high-resolution MS/MS in Supplementary Figure S1) for the modified peptide from rat dimethylaniline (N-oxide forming) monooxygenase, which was confirmed in all four rat livers by LC-MRM. This protein had been added to the LC-MRM method due to its presence as an APAP target in TPDB (Leeming et al., 2017). The same modification site that was previously found was confirmed.

DISCUSSION

Comparison of Targeted and Untargeted Workflows

Targeted LC-MS/MS workflows were specifically designed to utilize the high duty cycle and low limit of detection of multiple reaction monitoring (MRM). The detection of modified peptides was optimized using scheduled MRM methods built for each SPE fraction for a given species separately. By using HP-IAM in the reference samples, it was possible to mimic APAP-derived covalent modification on cysteines in the final protein digest. HP-CAM peptides were used to confirm which fractions to monitor for each modified peptide, as well as LC retention time and MS/MS fragmentation behavior, with relatively high signal intensity. Whenever possible, peptide candidates in one species were translated to the closest protein ortholog in the other species. Modified peptides not amenable to MRM transition development were omitted in the

799 final scheduled MRM method, based on giving an appropriate
800 signal for three MRM transitions in reference samples.

801 In general, targeted LC-MRM analyses showed far superior
802 detectability of APAP-modified peptides in these samples. An
803 important advantage that MRM detection has over data-
804 dependent MS/MS, is that each modified peptide signal is
805 continuously monitored, instead of depending on the
806 automatic selection of a precursor of interest for MS/MS
807 acquisition, which leads unfortunately to much less
808 reproducible data as well as the loss of low-abundant peptides
809 in highly complex samples. For this reason, many modified
810 peptides would not have a chance of being identified with
811 conventional untargeted bottom-up proteomics workflows. An
812 important caveat to the MRM method, however, is that method
813 development is more time-consuming, and in the case of APAP-
814 modified peptides for this study, the custom alkylation HP-CAM
815 peptides were crucial for confirmation. Also, MRM sensitivity
816 depends highly on the fragmentation behavior of the ionized
817 peptide. Certain highly charged or large peptides necessitate more
818 optimization by changing collision energies and selected multiple
819 fragment ions, and without an appropriate standard, this is
820 impossible. High-resolution DDA experiments are more
821 flexible, for example for those with multiple cysteines with
822 only one being modified by APAP. A unique opportunity was
823 afforded to specifically design LC-MRM assays for confirming
824 protein targets by the possibility of having a positional isomer of
825 APAP quantitatively modifying all cysteines in the liver
826 homogenates. Without this standard as a reference, these hits
827 may have been detected but not as easily confirmed.

829 Confirmed APAP Protein Targets

830 The aim of this study was to identify protein targets of APAP's
831 reactive metabolite in mouse and rat liver to help better
832 understand the mechanisms of APAP-induced hepatotoxicity.
833 Using a combination of high-resolution data-dependent MS/MS
834 and scheduled MRM experiments, a multitude of targets have
835 been found for the first time, as well as confirming others
836 previously reported targets of acetaminophen from literature.
837 It was possible to compare protein targets and modification sites
838 in mouse and rat livers. **Figure 3** summarizes the proteins
839 confirmed in this study, with those overlapping between both
840 species. All those listed were confirmed by LC-MRM analyses,
841 except protein/nucleic acid deglycase DJ-1, which was found by
842 data-dependent analyses in both species, however the modified
843 peptide was not amenable to MRM analysis. What was quite
844 striking was that for all proteins common to both species, the
845 same modification sites were confirmed. This suggests the
846 selective modification from APAP on these proteins, some of
847 which could be specifically involved in the mechanism of drug-
848 induced liver injury. Of the 24 protein groups listed in **Figure 3**,
849 17 were initially identified by DDA experiments and 12 were
850 listed as APAP targets in TPDB. Though not reported as APAP
851 targets, a few were also noted in TPDB as targets of other
852 xenobiotics.

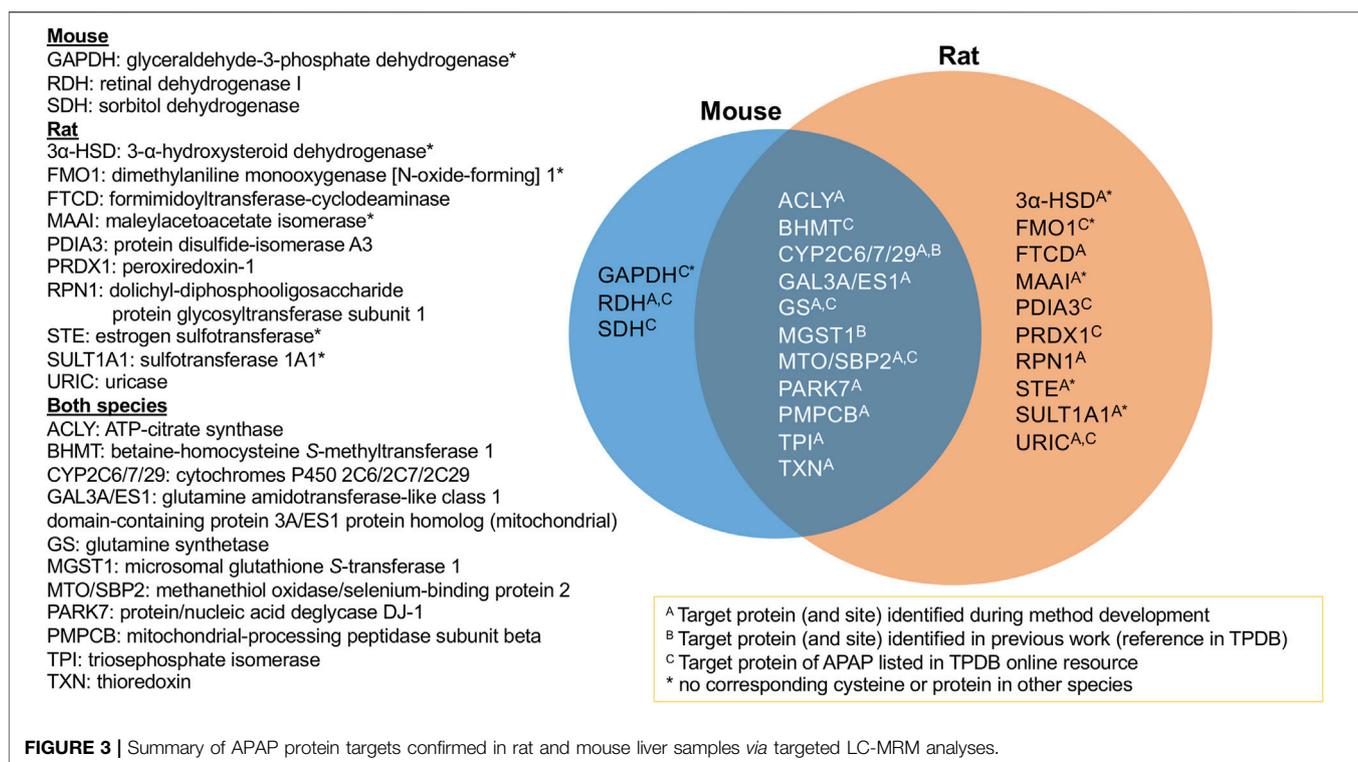

853 From the 10 protein targets confirmed in rat only, four of these
854 did not have corresponding cysteine residues in the mouse
855 ortholog, namely two sulfotransferases, dimethylaniline

856 monooxygenase and maleylacetoacetate isomerase. One other
857 protein, 3- α hydroxysteroid dehydrogenase (3 α -HSD),
858 does not have a corresponding ortholog in mouse at all. In the
859 case of the three targets found uniquely in mouse, one protein has
860 no corresponding cysteine in the rat protein (GAPDH). Retinal
861 dehydrogenase, though the same peptide was monitored for both
862 species, was only found in two of the eight mouse samples. As for
863 sorbitol dehydrogenase, the corresponding ortholog peptide was
864 not incorporated into the MRM method, since it was not found in
865 the rat HP-CAM reference sample and thus could not be
866 optimized in the targeted method.

867 One example of an APAP target found in rat, with no
868 corresponding cysteine in the mouse ortholog, was estrogen
869 sulfotransferase (EST), a cytosolic enzyme that inhibits
870 estrogen activity by conjugating a sulfonate group to it (Strott,
871 1996). The APAP-modified peptide
872 NNPC²³⁷TNYSMLPETMIDLK, which is common to rat
873 estrogen sulfotransferase isoforms 1, two or 3, was identified
874 by data-dependent experiments, as well as confirmed by LC-
875 MRM. Similarly, modified rat sulfotransferase 1A1 was found
876 from data-dependant experiments, and was also confirmed by
877 LC-MRM.

878 3 α -HSD catalyzes NAD(P)⁺-dependent oxidoreduction of
879 steroids and dihydrodiols. Multiple forms of 3 α -HSD have
880 been identified in rat liver with a role in xenobiotic
881 metabolism and intracellular transport of bile acids (Turley
882 and Dietschy, 1978). In rat liver, 3 α -HSD can metabolize
883 polycyclic aromatic hydrocarbon carcinogens and also affects
884 net bile acid transport across hepatocyte (Dufort et al., 2001).
885 Although not previously found to be a target of APAP binding,
886 3 α -HSD has been identified as a target of bromobenzene (Koen
887 et al., 2007), thiobenzamide (Ikehata et al., 2008) and furan (Moro
888 et al., 2012), without site specificity noted. From this study,
889 Cys170 was confirmed as the APAP modification site.

890 All 11 protein groups confirmed in both species (**Figure 3**) had
891 the same cysteine modification sites. ATP-citrate synthase
892 (ACLY) was found to be a target of acetaminophen in both
893 species by LC-MRM, following initial identification of the
894 modified rat peptide *via* data-dependent MS/MS. The
895 modified residue Cys20 is in its ATP-binding domain, which
896 catalyzes the conversion of citrate to acetyl-CoA in the TCA cycle.
897 Glutamine synthetase (GS) is a cytosolic enzyme, also associated
898 to mitochondria and ER. GS was previously identified as an
899 APAP target by immunochemical detection in mice (Bulera et al.,
900 1995). Its enzymatic activity was also significantly decreased by
901 APAP in cultured hepatocytes. After identifying the Cys269
902 modification site by data-dependent MS/MS in mouse, the
903 APAP peptide was confirmed in both species by LC-MRM.
904 Triosephosphate isomerase (TPI) is a glycolytic enzyme
905 necessary for energy production. Cytoplasmic TPI has been
906 reported as a covalent target of bromobenzene (Koen et al.,
907 2007), mycophenolic acid (Asif et al., 2007),
908 diaminochlorotriazine (Dooley et al., 2008), 4-bromophenol
909 (Koen et al., 2012), tienilic acid (Methogo et al., 2007) and
910 thioacetamide (Koen et al., 2013). Although TPI was only
911 confirmed by LC-MRM for the doubly APAP-modified
912 peptide in rat, it was also found to be singly modified at the

same site in both species *via* data-dependent experiments. It, therefore, was classified as a target of APAP in both species.

Rat ES1 protein homolog and mouse glutamine amidotransferase-like class 1 domain-containing protein 3A are orthologous mitochondrial proteins confirmed as modified in both species from these results. ES1 was found to be elevated in Down's syndrome, potentially as an antioxidant response to increased mitochondrial ROS production (Shin et al., 2004). Other mitochondrial protein targets confirmed in both species were mitochondrial-processing peptidase subunit beta (PMPCB), responsible for the proteolytic processing of mitochondrially encoded precursor polypeptides, and protein/nucleic acid deglycase DJ-1, also known as Parkinson disease protein 7 homolog, PARK7. PARK7 catalyzes the deglycation of Maillard adducts between proteins or DNA and reactive carbonyls (Richarme et al., 2015; Richarme et al., 2017) and protects cells from H₂O₂-related death (Sekito et al., 2006). It is required for correct mitochondrial morphology and function. The same modification site (Cys106) of PARK7 was recently found following APAP treatment of liver microtissues using data-independent MS/MS acquisition (Bruderer et al., 2015). Mitochondrial protein targets are of specific interest, as they have been correlated to the initiation of APAP's hepatotoxicity (Tirmenstein and Nelson, 1989; Ramachandran and Jaeschke, 2019). They have been proposed as a source of APAP-induced mitochondrial dysfunction (Hu et al., 2016), and are believed to be linked to the inhibition of electron transport chain (Lee et al., 2015), reactive oxygen species formation (Jiang et al., 2015) and mitogen-activated protein kinase and c-Jun N terminal kinase activation (Nguyen et al., 2021).

Two protein targets found previously by our group *in vitro* in rat liver microsomes, CYP2C6 and MGST1, were also confirmed here. Therefore, further *in vitro* work could be of value for finding biologically relevant targets in other cellular compartments, such as the cytosol and mitochondria. MGST1 had a common APAP-modified peptide in both species confirmed by LC-MRM. Orthologs CYP2C6 and 2C7 in rat, and 2C29 in mouse, were all found to be modified at Cys372 by APAP from data-dependent and MRM experiments. The latter two were consistently found as positive hits by LC-MRM in all animals of their respective species.

Other protein targets common to both species included betaine-homocysteine S-methyltransferase 1 (BHMT), methanethiol oxidase (MTO)/selenium binding protein 2 (SBP2) and thioredoxin (TXN). BHMT catalyzes betaine conversion to homocysteine in the biosynthesis of dimethylglycine and methionine. BHMT deficiency has been linked to hepatocellular carcinoma and fatty liver disease (Teng et al., 2011). BHMT was monitored as a potential target due to its presence in the TPDB list of APAP protein targets (Leeming et al., 2017), and confirmed the previously elucidated modification site. MTO and SBP2 are selenium-binding proteins, previously reported as major APAP targets in the liver (Bartolone et al., 1992; Pumford et al., 1992; Qiu et al., 1998) as well as other xenobiotics (Shipkova et al., 2004; Koen et al., 2007; Meier et al., 2007; Koen et al., 2012). Involved in organo-sulfur degradation, these proteins may be involved in the sensing of reactive xenobiotics in the cytoplasm (Pol et al., 2018).

Thioredoxin is involved in redox signalling through oxidation of its thiols. The APAP modification site was confirmed on Cys73, the only available free thiol in fully oxidized THX, which is also known

1027 to serve as a donor for nitrosylation of proteins under NO stress
1028 (Mitchell and Marletta, 2005). APAP overdose-linked oxidation of
1029 TXN2 has been previously observed (Ramachandran et al., 2015).
1030 Mitochondrial TXN2 and cytosolic TXN1 have been shown to be
1031 irreversibly modified by APAP (Jan et al., 2014). APAP-induced
1032 oxidation of cytosolic TXN1 results in the dissociation of TXN1 and
1033 its binding partner, apoptosis signal-regulating kinase 1 (Nakagawa
1034 et al., 2008). A protective effect of administration of albumin-fused
1035 recombinant TXN1, 4 h after APAP administration, has also been
1036 reported (Tanaka et al., 2014). Interestingly, this is the first report of
1037 APAP covalent binding to TXN, though it has been found as a
1038 target of other reactive metabolites (Koen et al., 2007; Ikehata et al.,
1039 2008; Moro et al., 2012; Koen et al., 2013).

1040 Reactive metabolites can covalently bind to proteins causing
1041 downstream immune reactions and/or cell damage (Poprac et al.,
1042 2017). APAP protein adduction has long been studied and serves
1043 as a model of drug-induced hepatotoxicity, however, its
1044 mechanism of action is not yet fully understood (Heard et al.,
1045 2016). Results from this study confirmed many previously
1046 reported protein targets, as well as their specific modification
1047 sites, and adding several new *in vivo* protein targets in two rodent
1048 models. These findings can be further investigated by studying
1049 protein and/or site-specific effects and mechanisms related to
1050 drug-induced toxicity. Mitochondrial protein targets of APAP
1051 would be of specific interest for subsequent research since there is
1052 already much evidence of mitochondrial signalling is involved in
1053 APAP hepatotoxicity.

1054 CONCLUSION

1055 An analytical workflow was developed and applied to rat and
1056 mouse liver homogenates to investigate protein covalent binding
1057 following APAP administration. Using a combination of high-
1058 resolution MS/MS and scheduled MRM assays for proteomic
1059 analyses and a custom alkylation reagent, many *in vivo* protein
1060 targets and their modification sites in both species have been
1061 confirmed or newly identified. The protein targets identified
1062 could serve to better understand the reactivity of NAPQI *in*
1063 *vivo* and could point towards specific targets of interest linked to
1064 acetaminophen-related hepatotoxicity. The performance of
1065 targeted scheduled LC-MRM has been demonstrated, based on
1066 a curated list of potential candidates, as a powerful tool in LC-MS/
1067 MS proteomics of low-abundant modified peptides in highly
1068 complex biological samples.
